The Department of the Navy

Prepared for

PREFACE

This Note reports work undertaken by Rand under the sponsorship of the Assistant Secretary of the Navy (Shipbuilding and Logistics). This work is part of a broader, continuing effort to enhance the integration and responsiveness of the naval aviation logistics system. This Note discusses alternative stockage computational techniques for aviation spares. It compares the estimated effectiveness of the resulting stockage postures with an emulation of the Navy's current techniques using the same investment levels.

Included here is a discussion of the levels of demand variability in the current system, and of the implications of that variability for flexibility and responsiveness, especially in combat.

The Note should be of interest to logistics managers and policymakers in naval aviation.

SUMMARY

This work evaluates alternative stockage computational techniques for aviation spares and estimates the levels of weapon system availability that might be achieved by the resulting stockage postures. The alternative methods are compared on an equal-cost basis with an emulation of the Navy's current approach. Although our demonstration and evaluation are quite simplistic and cannot be translated directly to the "real world," the numerical results are sufficiently dramatic to suggest that the recommended alternative approach is worth additional research and evaluation by the Navy. The recommended approach seems clearly superior to the current techniques used by the Navy to compute wholesale reorder levels and retail allowances for aviation repairable spares.

During the course of this research, we also examined 3M data from the Navy's aviation maintenance data collection system on several arbitrarily selected, weapon-replaceable assemblies (WRAs) on the F-14 aircraft. The data revealed levels of demand variability far beyond the levels planned for in determining allowances. This finding, however preliminary and tentative, implies the need for enhanced flexibility and responsiveness in aviation logistics as well as modified views of stockage policies and spares requirements determinations.

IMPROVING STOCKAGE POSTURES FOR AVIATION SPARES

In the course of our evaluation of alternative stockage computational methods, we developed a way to apply a multi-echelon optimization model that deals jointly with the wholesale and retail echelons to the Navy's aviation spares stockage problem. The optimization algorithm maximizes weapon system availability. The use of weapon system availability goals for management purposes has greater operational meaning than supply material availability or point-of-entry fill rates. The implementation of weapon system availability management in the Navy could significantly enhance the integration of requirements determination, programming, budgeting, and the day-to-day management of

the supply system, and could strengthen the cross-functional integration of supply and other functional areas.

The demonstration of alternative stockage computational methods is not entirely conclusive, but the magnitudes of several of the results suggest that the Navy might be able to achieve substantial improvements in weapon system availability with current levels of investment. The demonstration also suggests several other important observations:

- A stockage computational method based on realistic wartime scenarios will deliver better performance than one based on peacetime flying hour programs with war reserve, range, and other additives.
- The partition that exists between retail and wholesale stockage computations in the Navy seriously inhibits cost-effective solutions.
- If retail and wholesale stockage computations must be done separately, it may be important to future system improvement initiatives that the gains achievable through optimization of wholesale reorder levels are seriously constrained by retail allowances; bigger gains are achievable at the retail level but depend on a multi-echelon view.
- The use of an aircraft availability objective function coupled with a multi-echelon optimization algorithm is clearly superior to the Navy's current computational methods.
- Any stockage computational method should be used jointly with a capability assessment model that explicitly accounts for the dynamic character of combat scenarios to estimate the wartime performance of the resulting stockage postures.
- A multi-echelon optimization algorithm that maximizes pooled availability cannot be applied in a straightforward manner to the Navy's stockage computational problem, even if it accounts for heterogeneous distributions of end items, because it penalizes sites with smaller numbers of aircraft. It must also provide for separate optimization of AVCAL and OSI allowances. This will allow for provisioning each CV and NAS separately in addition to enabling availability rates to be balanced as

desired among retail sites, while still achieving most of the advantage of the multi-echelon technique.

The logic underlying the demonstration in this Note can be extended to the initial provisioning problem [11] as well as to stockage problems involving consumables. This Note also discusses some implementation issues associated with the improved technique.

ENHANCING RESPONSIVENESS IN AVIATION LOGISTICS

The computation of retail allowances is currently based on the classical assumption of a simple Poisson process. Under this assumption the variance of the demand distribution equals its mean, i.e., the variance-to-mean ratio is unity. This assumption is important to the computation of safety levels and to estimates of stockage posture performance characteristics such as fill rates, expected backorders, operational rates, and weapon system availability. It is a measure of the uncertainty of demand. The higher the variance-to-mean ratio, the less predictable the demand.

Of the 26 F-14 components selected for examination here, 19 of them had observed demand variability at least five times as great as assumed in the computation of retail allowances. Even after correction for flying hours, 19 of the 26 had at least twice the assumed variability.

The implication of variability of this magnitude is that it is very difficult to forecast demands, even in the short term. Yet the system presupposes the ability to make such forecasts, and behaves as though past demands predict future demands and peacetime demands predict wartime demands. The uncertainties in the system even in peacetime refute that supposition. Moreover, the uncertainties in peacetime will be compounded by the disruptions, resource losses, and inevitable surprises of combat. Thus it may be unwise to depend on a spares solution alone to the problem because of the substantially higher costs associated with stockage postures that try to provide a hedge against the demand variability. The need exists to examine other solutions involving more flexible resources than spares, such as maintenance and distribution/transportation.

Demand uncertainty of this magnitude implies the need for enhanced flexibility and responsiveness in the naval aviation logistics system, responsiveness which presupposes a level of integration that the Navy does not now enjoy. Thus the thrust of this work in stockage computational techniques should be viewed in the broader context of the enhanced integration needed in the system as a prerequisite of sorts to improving the system's flexibility and responsiveness. Its implications in the larger context are both for aviation supply within itself and for the interrelationships between supply and other functional areas.

But what of the implications for stockage computations of the levels of demand variability we have shown here? No matter how responsive the system can be made, the stockage computational problem never disappears. There will always be a need for spares. The question is how to formulate a reasonable set of assumptions on which to base the computational approach, including assumptions that take advantage of what we know about demand variability. If the levels of variability we have shown here are pervasive, their use in stockage computations might very well put stockage solutions that take explicit account of the variability out of reach in terms of their costs.

On the other hand, there may be a simple method for taking explicit account of demand variability in stockage computations in a way that does not make the solutions exorbitantly costly but does yield stockage postures that are sufficiently robust in the face of uncertainty. The solution to this problem is not yet clear. Additional analysis is needed to determine the extent and magnitude of the variability as well as its persistence over time. We also need to understand better the implications of the variability for stockage computations.

The cost of hedging against the levels of uncertainty that we have seen here might be more than offset by pursuing strategies that reduce item pipelines and that enhance the selective responsiveness of the system to unanticipated demands. In other words, system performance might best be enhanced by combinations of techniques that (a) take explicit account of uncertainty in stockage computations, (b) reduce component repair times, order-and-ship times, and retrograde times, and (c) enhance the ability of the system to respond selectively to

unanticipated demands in ways that contribute best to the combat posture of the fleet. Thus the observations made here about demand variability do not necessarily mean that optimization models are inappropriate for use in stockage computations because of the difficulty in forecasting demand. They simply imply that we need to understand the character of the variability better as well as its implications for stockage computations, and that solutions should be sought in other areas as well as in supply.

This argument is reinforced by the fact that the uncertainties the system faces in peacetime are compounded by the uncertainties of combat. The reduction of item pipelines and an enhanced ability to respond to unanticipated demands, coupled with improved stockage computational methods, can mitigate the effects of those uncertainties.

A RESEARCH PROGRAM IN INTEGRATION AND RESPONSIVENESS

This Note also proposes a program of research and development to be undertaken by the Navy the objectives of which are to:

- Implement capability assessment techniques at key decision points throughout naval aviation, including stockage determinations, to enhance system integration.
- Understand better the implications of uncertainty to the stockage computational problem.
- Develop multi-echelon spares stockage optimization models for computing wholesale reorder levels and retail allowances that maximize weapon system availability and that are consistent with the outcomes of the research in uncertainty.
- Develop integrated data bases that bring together the data required to support such computational techniques including military essentiality data.
- Develop strategies for improving the responsiveness of depot repair and distribution/transportation, thus coupling the depot more closely to the combat force to meet unanticipated critical demands more responsively.

ACKNOWLEDGMENTS

The authors are indebted to Mr. Frank W. Swofford of the Office of the Assistant Secretary of the Navy (Shipbuilding and Logistics) for his continuing encouragement and support; to Capt. E. M. Straw, Jr., SC, USN, Ms. Peggy McCormick, Mr. Kevin Boyle, and Ms. Fran Ziegler of the Aviation Supply Office for their very helpful interest and support; to Mr. M. Pierucci and his staff of the Navy Ships Parts Control Center for the 3M data summarized in Section V; to Mr. Paul Venzlowsky of the Naval Air Systems Command for his review and criticism; and to their colleagues at Rand, Dr. Morton B. Berman, Mr. I. K. Cohen, Dr. Gordon B. Crawford, Dr. Lloyd B. Embry, Dr. Zachary F. Lansdowne and Mr. Thomas F. Lippiatt, for their helpful comments and suggestions during the course of this research. Dr. Louis W. Miller provided a very careful and constructive review of the manuscript. Dr. Richard J. Hillestad of Rand authored the software used to emulate the Navy's computations of retail allowances. Pat Boren and Patti Dey, also of Rand, contributed significantly with data processing support.

We owe a special intellectual debt to Mr. I. K. Cohen of Rand, whose creative and imaginative ideas underlie the discussions in Sections I and V. We are also especially grateful to Dr. Gordon B. Crawford, whose ongoing research provided the stimulus for the analysis in Section V.

1. INTRODUCTION

The work discussed in this Note has its roots in a larger body of work on the integration of naval aviation logistics the theme of which was articulated in an earlier Rand Note [1]. In particular, the present Note focuses on the aviation supply system, especially the Navy's approach to aviation spares requirements determination, and addresses issues of integration both within the aviation supply system and across supply and other functional areas. More importantly, perhaps, the need for enhanced responsiveness and flexibility in Naval aviation logistics is implied strongly by the findings of this work. Although its primary focus is on component-related issues, it has implications for other resources.

The observations made in this Note reinforce the findings of earlier Rand work for the Navy in the Carrier Based Air Logistics (CABAL) Study [2,3], which examined the value of an aircraft availability objective function in computing spares stockage requirements for aircraft carriers; however, the earlier work did not examine the value of multi-echelon computational techniques as this work does. Rand is also involved in ongoing work, still unpublished, to understand better the implications of variability in resource demands for stockage computations and other, broader logistics system issues that we discuss at length in Section V.

At the expense of brevity, we repeat the essential theme of Ref. 1 in the discussion that follows. The reader familiar with the earlier Note is invited to continue reading on page 5, under the heading What Follows.

AN INTEGRATED VIEW OF NAVAL AVIATION LOGISTICS

The integration theme is conceptually straightforward, albeit complicated in implementation. The ultimate outputs of the aviation logistics system are peacetime readiness and combat sustainability. What we mean by *integration* is the quality of a system each of whose subsystems, echelons, organizations, decision processes, goals,

objective functions, performance measures, and policies are mutually consistent and oriented toward the ultimate outputs of the total system. The implicit assumption in this view is that resources can thereby be balanced in a way that enables the system to achieve its ultimate goals most efficiently.

The decisionmaking, goal setting, and resource allocations of the planning, programming, budgeting, and budget execution (PPB&E) process are intended to balance the required levels of readiness and sustainability with force structure and modernization needs while meeting fiscal resource constraints. Ideally, the specification of readiness and sustainability goals would be done with full visibility of the costs of achieving them, and the execution process would allocate expenditures in ways that maximize the readiness and sustainability achievable for any specified level of investment. Moreover, again in an ideal world, the characteristics of the operational logistics system would be such that readiness and sustainability would be maximized within the fiscal resource constraints established in the PPB&E process.

In the face of the vagaries and imperfections of the real world, such an idealized view of a perfectly integrated system may seem naive, but, nevertheless, it is a useful conceptual model in understanding how to move toward a total system that will at least better achieve adequate levels of military capability at minimal levels of investment. An idealized view, when contrasted with the current system, helps identify the specific enhancements needed to the decisionmaking process in the PPB&E context as well as the specific improvements needed in the operational logistics system.

Planning, Programming, Budgeting, Execution, and Management

Figure 1 portrays a conceptual model of an idealized system and illustrates its complexities. It extends beyond the resource allocation of the PPB&E process to include the resource management of operational logistics, hence the added dimension of management and the term PPBE&M. The idealized system provides for feedback of management information from operational logistics to the PPB&E process to support the planning and resource allocation decisionmaking involved in establishing readiness and sustainability goals and fiscal constraints.

Planning, programming, budgeting, and management: an integrated process

Fig. 1 — A conceptual model of the PPBE & M process

The role of planning is suggested in Figure 1 by the block at the left. The defense guidance and force structure are exogenous inputs to the process insofar as logistics support resources are concerned. The term capability assessment is included in each of the several major blocks representing the stages of planning, programming, budgeting and budget execution. Capability assessment is the estimation of military capability given a scenario and a particular set of support resources, policies, and logistics system characteristics. The arrows within the blocks portray the important role of capability assessment as an integral part of the decisionmaking at each stage. The concept we intend to convey is that capability assessment tools are useful not only in evaluating decision alternatives but also in formulating additional alternatives.

The decisionmaking at each stage should be consistent in terms of capability goals with the decisions made at every other stage. The use of capability assessments at each stage helps assure that consistency.

Capability goals are not represented as the product of any particular stage of the process; rather, the decisions made at each stage involve tradeoffs among resources, adjustments in investment levels, reexamination of the balance among resources, and the effects of such decisions on capability. Therefore, although capability goals may be thought of as emerging from the planning stage, they may be adjusted by subsequent decisions in later stages.

The Central Role of Requirements Systems in PPBE&M

Requirements systems have a central role in PPBE&M processes. A clear understanding of that role helps illuminate specific needs for enhanced integration, coordination, and control across all stages of the process as well as within each individual stage. Requirements determinations are first made within functional areas using computational methods that must be consistent with the execution system that will ultimately be used to allocate the fiscal resources that eventually emerge from the budgeting stage. It is essentially a "bottom-up" approach to the resource allocation process. However, it is encumbered by the fact that the original statement of requirements by the functional area consists of a single-valued requirement that is typically not determined on the basis of a computation that explicitly relates the requirement to a direct measure of military capability.

In addition, the single requirement as now computed is not based upon any commonly understood measure directly related to the operational performance of the total system; i.e., the secondary measures now in use, such as supply materiel availability rates or point-of-entry fill rates, are not directly related to measures of combat readiness or sustainability. The most compelling argument in favor of any statement of requirements is an explication of the relationship between the recommended requirement and the level of military capability it will deliver, thus making visible what changing or underfunding it will mean to the readiness and sustainability of the combat force.

One can raise serious questions regarding the validity of a requirements determination process in which a single requirement is computed ("the" requirement), rather than a range of alternatives each with an associated cost and capability level. Unfortunately, the Navy

does not now have convenient means for exploring wide ranges of alternative levels of capability and investment without resorting in many cases to complex, costly, and time-consuming requirements computations. We explore these issues further in Section II in the context of the aviation spares requirements system.

The lack of mechanisms for assessing the capability that will be produced by specific mixes of resources, support system characteristics, and policies, given some scenario of interest, underlies many of the difficulties faced by the Navy in the PPBS process. For example, if there is no mechanism in the programming stage for relating requirements to capability, then the POM input may be viewed as largely arbitrary in the sense that the requirements it reflects are based on some intermediate (or functionally oriented) performance goals that the system sets for itself, rather than meaningful measures of military capability. Moreover, the same need exists at every stage of the process if resource allocation decisionmaking is ever going to become explicitly capability oriented.

WHAT FOLLOWS

In the remainder of this Note, we explore the application of these ideas to the Navy's aviation logistics system, especially its spares requirements determination process. In Section II we discuss the Navy's current spares requirements systems and stockage policies. In Section III we provide a simple demonstration of the value of an aircraft availability objective function coupled with a multi-echelon optimization algorithm for determining aviation spares stockage postures, and address some of the implementation problems involved with such techniques in Section IV. We return to broader, system-level considerations in Section V, where we explore the implications of uncertainty for the resource allocation process as well as operational logistics. In Section VI we suggest strategies for enhancing integration and responsiveness in the aviation logistics system.

II. SPARES STOCKAGE DETERMINATION AND STOCKAGE POLICIES IN NAVAL AVIATION

Three important characteristics of naval aviation supply inhibit the achievement of a truly integrated and responsive system. These characteristics are:

- Spares stockage computations for the wholesale and retail echelons of the system are partitioned from each other in important ways.
- Fill rates are used as objective functions, goals, and performance measures.
- Stockage policies are essentially demand-based.

THE PARTITIONED NATURE OF SPARES REQUIREMENTS DETERMINATIONS

In many ways the wholesale and retail echelons are viewed as being separate and distinct from each other. This point of view is taken in the spares requirements determination process and is implemented in a way that inhibits the achievement of the best balance of investments and resource allocations across echelons. In the wholesale requirements process, for example, no explicit consideration is given to the organizational and intermediate level pipeline or to retail allowances except as planned requirements. Similarly, retail allowances are computed without visibility of wholesale reorder levels or expected delays in resupply from the wholesale echelon.

Evidence suggests that the lack of a multi-echelon orientation in the levels computation and requirements process and, indeed, in supply system management, results in lower levels of system performance than could otherwise be achieved with current levels of investment. In Section III we try to provide some intuition about the magnitude of gains achievable from various multi-echelon approaches to spares stockage computations.

THE CURRENT SPARES STOCKAGE SYSTEM

Again at the expense of brevity, we describe the key attributes of the Navy's current spares stockage determination process to provide the motivation for the assessment of alternative approaches described in Section III. The discussion in the remainder of this section draws heavily from [1].

Wholesale Requirements and Reorder Levels

The determination of wholesale reorder levels and wholesale stockage investment levels depends upon three different computational systems. These three distinct but logically equivalent systems are: Stratification (Strat); the Leadtime Computation, Demand Forecasting, Activity Stocking Criteria and Levels Computation (Levels); and Supply Demand Review (SDR) [4-7].

Strat estimates requirements for POM and budget purposes and is a longer-range computation than is the SDR. It is run semiannually. A supporting system, the Computation and Research Evaluation System (CARES), simulates Strat and operates on a sample data base. It is designed to help decisionmakers determine desirable values of input parameters to Strat and Levels.

The Levels computation is the second principal ingredient of the system. It is run quarterly to update estimates of component characteristics such as demand rates and pipeline times. On the basis of these estimates of item characteristics, Levels computes wholesale reorder levels. The computation is designed to minimize the sum of item holding plus shortage costs. The shortage costs are associated with an SMA rate goal.

SDR, the third major component of the system, computes requirements in the short term based on the Levels outputs, i.e., for actual procurement purposes rather than for POM input or budget planning purposes. It is run weekly for consumables and monthly for repairables.

Although weapon system application and program data are used in the computation of wholesale reorder levels, the objective function is strictly item-oriented rather than weapon-system-oriented. The result is that the set of wholesale reorder levels computed by the system does

not reflect weapon system complexity. A weapon system with a large number of components will therefore suffer lower levels of readiness than will weapon systems with relatively small numbers of components.

Retail Allowances

The process of retail provisioning involves the computation of stockage allowances that are reflected in Aviation Consolidated Allowance Lists (AVCALs) for aircraft carriers and in Operational Support Inventory (OSI) for naval air stations. The computation of these allowances takes no account of the wholesale stockage posture. (By stockage posture we mean a set of stock levels by item and location.) Yet, the expected resupply time experienced by, say, an aircraft carrier submitting a requisition to the central system depends on the total demand rate experienced by the wholesale system and on the wholesale reorder level (as well as other wholesale system characteristics). It is well known that, in a two-echelon inventory system, if the stockage posture at the lower echelon is computed in a way that explicitly accounts for the expected delay times in resupply from the higher level, it will yield higher levels of performance for specified levels of investment than will a computational method that ignores those delay times. This fact is demonstrated in Section III.

A Word About Data Bases

Strat, Levels, and CARES operate on data from various sources that reflect a large number of "component" characteristics; however, many parameters that are typically referred to as "component" characteristics are in reality performance measures of the logistics system. Such data elements as failure rate and unit cost are largely functions of the component itself; but repair times, order-and-ship times, removal rates, and BCM rates are determined largely by the structure, policies, and performance of the logistics system. In fact, even unit costs can be influenced dramatically by spares acquisition strategies. Thus data that are typically viewed as descriptive of components have much broader meaning and implications to the military programmer.

To the extent that such data elements influence resource requirements, they should be the objects of management scrutiny, not just for the sake of accuracy, but to make them a realistic model of future logistics system performance. It is insufficient to use historical observations as the sole basis for projecting future requirements, just as it is to use peacetime measures as the sole basis for forecasting wartime requirements. Moreover, management must ensure that the logistics system performs in ways that are consistent with that model, or that the inconsistencies and exceptions are made visible so that adjustments can be made in execution or operational management. The goal is to ensure that the military capability objectives intended in resourcing decisions are achieved in the operational environment.

OBJECTIVE FUNCTIONS, GOALS, AND PERFORMANCE MEASURES

The use of fill rates pervades the aviation supply system. Fill rates are used in establishing investment levels; they are used as goals; and they are used as measures of system performance. The fill rate measure is typical of functionally oriented measures. It is only indirectly related to readiness and sustainability. Although it is a simple measure and easily understood, it is not especially meaningful outside the supply system. More important, it is not operationally meaningful. The implication to readiness of a particular level of fill rate depends heavily on resupply time; thus an expected (time-weighted) backorder measure has more operational significance than fill rate. Unfortunately, the expected backorder measure is not as straightforward or as easily understood. But it, too, fails in the sense that it is only indirectly related to readiness, and it does not account for weapon system complexity as measured by the number of components per aircraft. Weapon system availability, on the other hand, although it does not quite convey the idea of "bombs on target," does measure very directly the end product of the logistics system: mission capable aircraft. Thus, it is a more ultimate measure of system performance than either expected backorders or fill rate. Moreover, it accounts explicitly for weapon system complexity. The specific model of weapon system availability underlying the computations and evaluations in this Note is discussed in Appendix C.

Fill rate is not actually the objective function in Levels or Strat. As pointed out previously, the computational system minimizes the sum of holding plus shortage costs by item; however, the shortage costs are exogenously specified to Levels and Strat, and fill rate is a principal focus of attention in the decisionmaking associated with the setting of those input parameters. Thus shortage costs act like surrogates for fill rate, and they can be adjusted through the use of CARES until the desired fill rate is obtained. In effect, then, fill rate really plays the role of a goal in stockage computations.

In a sense, the pervasive use of fill rates throughout the aviation supply system has some integrating value because its use as a performance measure is consistent with its use as a goal and with its use in the computational system. Unfortunately, its uniqueness to the supply system sharply diminishes its utility when requirements need to be communicated and justified to the rest of the logistics community and to others in the government. It is in this larger context that such intermediate or functionally oriented measures fail most visibly. It is also in this context that more ultimate measures, such as weapon system availability, are more persuasive. Fill rates are not expressive of weapon system readiness; weapon system availability rates are. To the extent that the relationships between fiscal resources and military readiness are important at the budget table, fill rates may fail and weapon system availability rates succeed in motivating the appropriate investment decision.

But the resource allocation arena is not the only context where measures like fill rates are dominated by more ultimate, capability-oriented measures. Clearly, if the use of a weapon system availability objective function in Levels or Strat will result in the setting of investment levels that are more appropriate, and in spares postures that deliver higher levels of readiness and sustainability for those investment levels, then it is to be preferred to the continued use of the current objective function.

A similar argument can be advanced in support of the use of weapon system availability rates as measures of system performance. They focus management attention on a more ultimate output of the system than simply its efficiency in filling requisitions. Thus we argue in favor of the use of weapon system availability rates as objective functions in spares requirements determination, in spares procurement, in component repair prioritization, and as goals and performance measures just as pervasive in character as fill rates are now.

STOCKAGE POLICIES IN NAVAL AVIATION

Stockage policies throughout the system are essentially demand based. The decision to stock or not stock an item is typically based solely on past demand. In some sense, that is an overstatement. Stockage criteria may differ by cognizance code (cog), and cogs differ by cost, expendability, etc. Less expensive consumables, for example, may have a more relaxed stockage criterion than more costly repairables. There are also special rules for insurance and numerical stockage objective (NSO) items. It is fair to say, however, that among all the characteristics of aircraft components, the use of demand rates as a basis for stockage decisions dominates all others.

The distribution of demands over weapon system components in naval aviation is concentrated over a fairly small proportion of the components. A large proportion of the line items in the system have very low or no observed demand over the time period of, say, the last two years. The important characteristic of a stockage posture that is determined on the basis of demand rate alone is its lack of range that results from the nature of the distribution of demands over line items. A demand-based stockage policy tends not to stock many of the items in the long tail of the distribution of demand rates over components; yet, in the aggregate, they constitute a substantial proportion of the total demand activity by sheer weight of the number of items involved.

One of the attractive features of a weapon system availability optimization model is that it stocks items on the basis of many of their characteristics rather than just demand rate. Therefore, many of the low demand items may be stocked by such a model if they are inexpensive or have long leadtimes, high BCM rates, long repair times, or high condemnation rates. The overall result is a stockage posture of considerably extended range that can be expected to deliver better performance for specified levels of investment.

In the next section, we point out some of the differences between the kind of stockage posture that results from the Navy's current computational methods and several alternative methods. Lest we lose sight of our broader perspective of an integrated system, we point out that our demonstration of alternative stockage computational methods is intended to illustrate the value of a capability-oriented objective function coupled with an integrated view of the logistics system. Thus we extend the logic of Sections I and II to a particular problem, that of computing stockage postures.

III. A SIMPLE DEMONSTRATION OF ALTERNATIVE STOCKAGE COMPUTATIONAL METHODS

In this section we describe a simple experiment in which we emulate the Navy's current spares stockage computations and compare the resulting stockage postures with stockage postures generated by alternative computational methods. The purpose of this experiment is simply to gain some intuition about the magnitude of gains in performance that might be achievable at current levels of investment by using alternative computational methods. Throughout this discussion we use the term availability to mean weapon system availability, not material availability. We define availability rate to mean the probability that an end item (in this case an aircraft) selected at random is not waiting for a part.

THE EXPERIMENTAL DESIGN

In past work for the Navy, Rand built computer software that emulates the Navy's computations of retail allowances for both AVCALs and OSI. In this current work we constructed additional software that emulates the Navy's computation of wholesale reorder levels. Both software packages are included in Appendix A for the interested reader. We use this software along with the actual shortage costs specified by ASO for the September 1983 Strat to compute a stockage posture. We specify certain scenario characteristics to this computation that we will describe later. The computation yields a stockage posture for the entire system consisting of aircraft carriers, naval air stations, and whol sale stockage points. The total investment level associated with this "Navy" stockage posture is then used as an investment constraint for all other computations. Thus throughout the experiment we compare equal-cost alternatives.

The experiment includes four other computational approaches:

- A wholesale reorder (stock) level optimization.
- An AVCAL and OSI allowance optimization.
- A multi-echelon optimization of pooled availability.
- A balanced multi-echelon optimization.

We describe each of these alternative approaches in greater detail later. What is important about them is that each uses an aircraft availability objective function, and each is, in some sense, a multi-echelon approach. (We clarify this later as well.) In addition to these four alternatives, we examine an AVCAL and OSI optimization technique that uses an aircraft availability objective function without the multi-echelon view.

THE DATA BASE

The data base for this demonstration consists only of repairable weapon-replaceable assemblies (WRAs) that apply to the F-14 aircraft. Because of data limitations, we assume that each of these items is peculiar to the F-14, i.e., we assign its total demand to the F-14. We could not infer the variance of the wholesale demand stream from available data; therefore, we assigned to each item a variance-to-mean ratio computed by the method described in Appendix B. These simplifying assumptions do not inhibit the comparison of the computational techniques; however, they do preclude translating the numerical results directly to the "real world."

The retrograde pipeline is not explicitly accounted for by the Navy's procedures. Assets are procured during the early life of a weapon system to cover the retrograde pipeline based on estimates of item characteristics and an assumption of 30 days retrograde time. Thereafter both the retrograde requirement and retrograde assets are ignored. Because of this, we excluded the retrograde pipeline from all computations since we felt that it would reflect adversely on the "Navy" computational technique. Moreover, the experiment ignores assets in the current system; it operates only with levels, i.e., wholesale reorder levels and AVCAL and OSI allowances.

The 3M system, the Navy's maintenance data collection system, was the source of item removal and BCM rates.

THE SCENARIO

The scenario used for the demonstration is only an abstraction of the Navy's actual force configuration. Thus it only approximates the dimensions of the stockage computational problem. It has characteristics that help clarify certain computational issues that are important to any eventual implementation. These issues will emerge in subsequent discussion. No attempt should be made to compare actual stock levels of components with those computed in this demonstration because of the abstractions of the scenario.

The scenario consists of two naval air stations, each with 150 aircraft, and four aircraft carriers (CVs), each with 24 aircraft. The order-and-ship time for all items is 25 days to the CVs and 10 days to the air stations. The aircraft utilization rates used were extracted from the Baseline Scenario. We explicitly assume throughout the demonstration that there is no lateral supply.

THE "NAVY" METHOD

We will describe our emulation of the Navy's stockage computational methods as the "Navy" method, implying with our use of quotation marks that our emulation may be imperfect. As we pointed out in Section II, the "Navy" method computes wholesale reorder levels without taking advantage of information about the retail level other than allowance shortages, planned requirements, and the demand stream from retail to wholesale. Similarly, it computes retail allowances without using information about the wholesale system, e.g., wholesale reorder levels, wholesale-level demand rates, or the expected wholesale delay time. Moreover, the "Navy" method minimizes the sum of holding plus shortage costs by item, rather than maximizing aircraft availability.

Using the software described in Appendix A, we emulated the Navy's computational method for the scenario described, then estimated the peacetime and wartime steady-state aircraft availability rates delivered by the resulting stockage posture. The results are shown in Table 1 and Figure 2. The availability rates in Table 1 were estimated using a

Table 1
EVALUATION OF "NAVY" STOCKAGE POSTURE

Ai	rcraft Ava	ailability
Pe	acetime	Wartime
Pooled	74	34
NAS	75	36
CV	72	32

model that makes no explicit assumption about cannibalization; rather, it assumes a random distribution of shortages over aircraft. The aircraft availability rate shown in Figure 2 was estimated with the Dyna-METRIC model which does not depend on steady-state assumptions [8]. It estimates aircraft availability in dynamic scenarios where activity

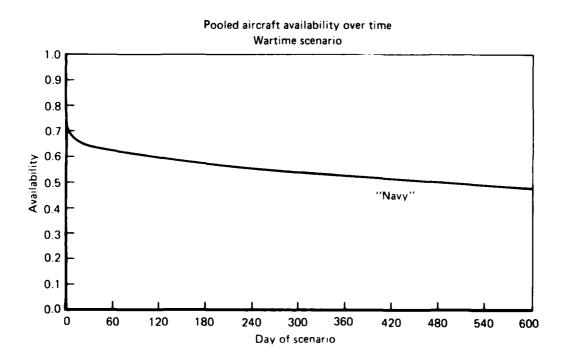

Fig. 2 - Aircraft availability over time, "Navy" stockage posture

levels may change dramatically over time. The model was applied in this case using the same assumption of randomly distributed shortages. It portrays the decline of the pooled aircraft availability rate after the wartime flying hour program begins. Clearly, it takes a long time for the availability rate to reach the steady-state value shown in Table 1. The implication of this observation is that a steady-state wartime formulation of the requirements problem may not make much sense. The dynamic character of the wartime scenario needs to be taken explicitly into account. Nevertheless, the levels of availability associated with the "Navy" stockage posture seem troublesome no matter how abstract the scenario.

It is important to point out that the estimated availability rate that might be achieved by the "Navy" stockage posture is considerably enhanced by cannibalization. The performance of this posture is improved more by cannibalization than is the performance of any of the other stockage postures evaluated in this experiment. The cost of the amount of cannibalization needed, however, is unknown but probably quite significant.

An important caveat about our evaluation of all of the stockage postures computed in this demonstration, but especially that of the "Navy" method, is that we assume variance-to-mean ratios according to the method described in Appendix B, the implication of which is that the "Navy" stockage posture is evaluated with higher variance-to-mean ratios than are assumed in the computation of retail allowances in the "Navy" method. For the other stockage postures, the variance-to-mean ratios used in the evaluation are the same as those assumed in the stockage posture computations. Thus one of the important differences between the "Navy" method and the alternatives examined here is the choice of variance-to-mean ratio to be assigned to the probability density function of the number of items in resupply of each type. It was not clear that this discrepancy could be avoided since the "Navy" method replicates the actual assumption made by the Navy in computing retail allowances.

OPTIMIZING WHOLESALE REORDER LEVELS ALONE

The first of the alternative computational methods optimizes wholesale reorder levels alone. The method involves the use of an aircraft availability objective function of the form described in Appendix C. Although the only decision variables involved in the optimization are the wholesale levels, the computation is done taking explicit account of retail allowances. Thus the method is a multiechelon computation in that sense, but makes no adjustment to the retail levels. The retail allowances used are those computed using the "Navy" method. The investment level used as a constraint at each echelon in this computation is the same as that of the "Navy" method. The estimated peacetime and wartime steady-state availability rates that result from this method are shown in Table 2.

These results suggest the magnitude of gains that might be achievable from a computational method involving only the wholesale reorder levels as decision variables. The CV wartime availability is still very low.

Table 2

EVALUATION OF WHOLESALE-ONLY OPTIMIZATION

Aircraft Availability		
	Wholesale Only	"Navy"
	Peacetime	
Pooled	79	74
NAS	80	75
cv	76	72
	Wartime	
Pooled	60	34
NAS	67	36
CV	46	32

The availability-cost curve of Figure 3 shows the flatness of the relationship between aircraft availability and investment level for the wholesale-only computation. The points shown are those associated with the "Navy" investment level.

The motivation for our original interest in this problem was the possibility of modifying ASO's requirements computations with a simple change requiring only modest cost, time, and effort that would bring a weapon system availability objective function to Strat and Levels. The relationship shown in Figure 3 led us to explore other alternatives.

OPTIMIZING RETAIL ALLOWANCES ALONE

It is clear from the example that follows that the partitioned character of the Navy's current computational technique can result in a serious imbalance in resource allocations across echelons of the system. The example consists of optimizing only retail allowances using an aircraft availability objective function and complete information about

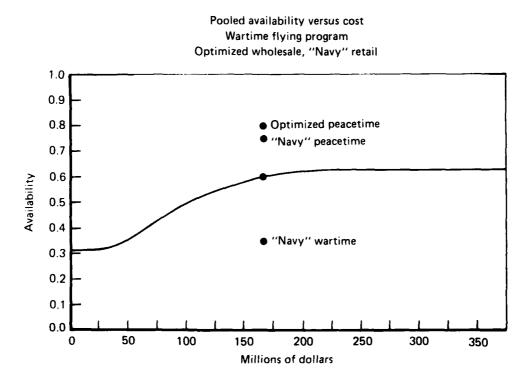

Fig. 3 - Availability/cost relationship, wholesale-only method

the wholesale stockage posture and demand stream. Thus it is another example of a multi-echelon approach in which the decision variables are at one echelon only. In this case, we use the same wholesale stockage posture and total investment level as in the "Navy" case. The estimated aircraft availability rates yielded by the resulting stockage posture are shown in Table 3.

Since this optimization was done using the wartime utilization rates, the CV peacetime availability is very high. Note, too, the substantially greater gains achievable with this method than with the wholesale-only approach, the availabilities for which have been included in Table 3 for comparative purposes. This result suggests that the partitioned character of the Navy's current computational techniques may lead to serious misallocations of resources across echelons of the system. We again point out that these "retail-only" results depend on taking explicit account of the wholesale stockage posture and demand stream in computing the retail levels.

CV	74	46	32			

MULTI-ECHELON OPTIMIZATION OF POOLED AVAILABILITY

In this step of the demonstration, we apply a multi-echelon optimization algorithm to the problem of optimizing all of the stock levels in the system, at both echelons and at all locations, again using an aircraft availability objective function. The algorithm allocates stock levels in a way that maximizes the pooled aircraft availability across all retail sites in the system while approximating for each item the optimal allocation of stock levels across echelons as well as across locations. The evaluation of the resulting stockage posture is shown in Table 4.

The pooled aircraft availability with this straightforward multiechelon approach is substantially higher than with any other approach. The problem is, however, that the CV availability is significantly lower than that for the NAS. The reason for this is that the number of aircraft in the CV deckload is so much smaller than the number at the NAS. In allocating stock levels, the optimization algorithm takes best advantage of this heterogeneous distribution of aircraft in maximizing the pooled availability. Hence the discrepancy. (The problem of

Table 4

constructing an efficient optimization algorithm that will maintain equal availability across heterogeneous sites is intractable.)

The relationship between the pooled wartime availability and the total investment associated with the multi-echelon optimization of pooled availability is shown in Figure 4 along with the estimated availability delivered by the "Navy" stockage posture. Again the reader is reminded that these are steady-state availabilities based on the assumption of randomly distributed shortages among aircraft.

A BALANCED MULTI-ECHELON COMPUTATION

The undesirable imbalance associated with the multi-echelon optimization of pooled availability led to the formulation of a modified approach to the application of the multi-echelon algorithm. This approach consists of the following steps:

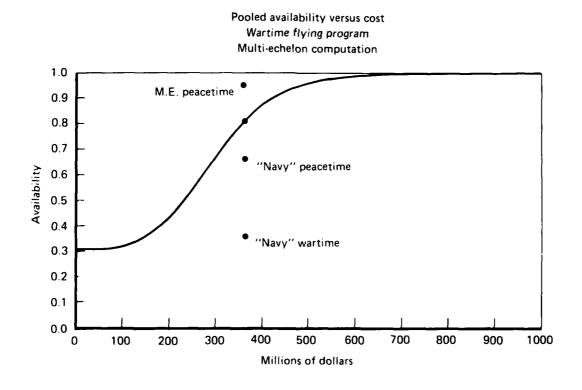

Fig. 4 — Availability/cost relationship, unconstrained multi-echelon method

- Run the straightforward multi-echelon optimization of pooled availability.
- Using the resulting availability/cost curve, select the point on the curve that is, in some sense, most desirable. For purposes of this demonstration we selected the point for which the investment level was equal to that of the "Navy" case.
- Fix the wholesale reorder levels equal to those associated with the stockage posture underlying the selected point.
- Reoptimize the AVCAL and OSI allowances using the "retailonly" approach previously described, thus enabling the CV and NAS availabilities to be established in such a way that the total investment level is still maintained but the availabilities are balanced acceptably.

For purposes of our demonstration, we chose to set the CV and NAS availability rates equal, keeping the total investment level the same as in all of the other cases. The results are shown in Table 5. The availability/cost curves are shown in Figure 5 and a Dyna-METRIC evaluation is portrayed in Figure 6 along with that of the "Navy" stockage posture for purposes of comparison.

The balanced approach has the attractive feature of allowing the decisionmaker to compensate for any heterogeneity in aircraft distribution although, obviously, some pooled availability is given up in the process.

The contrast between the balanced approach and the "retail-only" method previously described is especially interesting. In the "retail-only" method, you may recall, the wholesale stockage posture used was that of the "Navy" method, while in the balanced multi-echelon approach the wholesale stockage posture used was the one associated with the unconstrained multi-echelon computation. Thus the difference in these two approaches lies in the wholesale-level stockage posture alone. Recall, though, that both methods take full advantage of information about the wholesale level when optimizing retail allowances. Interestingly, in the balanced multi-echelon case, the wholesale stockage posture is optimized with full visibility of the retail level,

Table 5

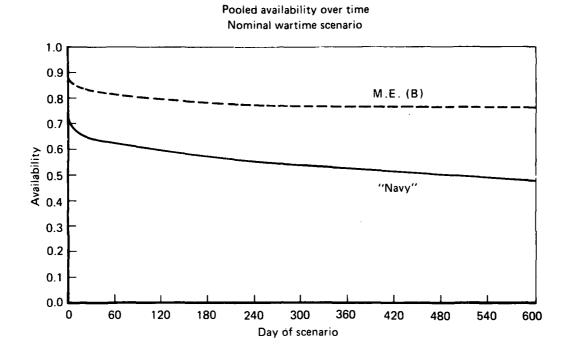

Fig. 6 - Aircraft availability over time, Navy versus balanced method

indeed of the entire system. In the "retail-only" case, on the other hand, the wholesale stockage posture is determined without using any information about retail allowances.

The remaining important research question of interest about optimizing retail allowances is how much of the overall availability gain is achieved through the use of an aircraft availability objective function and optimization algorithm, and how much through the use of complete information about the wholesale level. In other words, if we fix the wholesale stockage posture and optimize the AVCAL and OSI allowances using an aircraft availability objective function, how much can we gain without visibility of the wholesale level? The final steps in this experiment, which we describe in the discussion that follows, provide some intuition about this important question.

THE FUNDAMENTAL IMPORTANCE OF A MULTI-ECHELON VIEW

In the classical formulation of the multi-echelon inventory problem, the elapsed time experienced by a retail activity from the submission of a requisition to receipt of the item is the sum of two pipeline time segments: (a) the order-and-ship time and (b) the depot (wholesale) delay time [9]. The order-and-ship time is typically modeled as a constant based on actual experience. The depot delay time of an item is a mathematical expectation computed by dividing the depot expected backorders by the depot daily demand rate. Therefore, the total time that elapses from requisition to receipt depends in part on the wholesale reorder level of the item.

Obviously, the depot delay time is not the same for all items. If the wholesale level has unlimited stock of an item, the requisitioning activity will experience a total waiting time equal to the order-and-ship time. In the simplest case, if the wholesale level has no stock at all, the requisition will be delayed for the sum of the retrograde time, depot repair time, and order-and-ship time (assuming no condemnation action or procurement). The sum of expected delay time plus order-and-ship time ranges between these two extremes depending on the wholesale reorder level of the item.

The following experiment demonstrates the importance of taking explicit account of depot delay times by item when computing retail allowances.

Case 1

Consider first the case where the depot stockage posture is the same as that computed in the "Navy" case described earlier. We now compute AVCAL and OSI allowances using an aircraft availability objective function and optimization algorithm as before, but we ignore the information we have about the wholesale level and assume that all requisitions on the wholesale level are filled without delay, i.e., we assume a depot delay time of zero for all items. As before, the total investment level remains the same. The evaluation of the resulting stockage posture (made using full visibility of both echelons) is shown in Table 6.

Table 6

EVALUATION OF CASE 1

	Aircraf	t Availabili	ty
	Retail Only	Case 1	"Navy"
	Pea	cetime	
Pooled	88	89	74
NAS	86	87	75
CV	95	95	72
	War	time	
Pooled	74	47	34
NAS	74	46	36
CV	74	50	32

This is an especially important result because it suggests the magnitude of gain in aircraft availability that might be achieved by moving to the use of an aircraft availability objective function and optimization algorithm for computing retail allowances without using available information about the wholesale level. In other words, Case 1 is strictly a single-echelon computation, in the sense of both its lack of visibility of the other echelon and in the stock levels it uses as decision variables. The retail-only case described previously also optimizes only the retail stock levels as Case i does, but unlike Case 1, makes explicit use of information about the wholesale level, i.e., item-specific depot delay times. The retail-only case is included here for purposes of comparison because it isolates the effect of using item-specific depot delay times; that is the only difference between the two computations.

Another reason that the result of Case 1 is important. I that the Navy does not account for depot delay times in its current AVCAL and OSI computations, implicitly assigning a value of zero to all depot delay times.

Cases 2 and 3

In the second case, we repeat the computation of Case 1 with the single exception that, instead of using a depot delay time of zero for all items, we specify its value to be the weighted depot delay time over all items. In Case 3, we double this value, keeping all other things the same. Now, obviously, since the computation of the weighted depot delay time depends on knowing the item-specific times, we examine this case for didactic purposes only. The question we address here is simply this: if we specify a constant as the depot delay time for all items, does the value of that constant affect the performance of the resulting stockage posture? As Table 7 shows, the answer is yes.

It is not our purpose here to search for the "optimal" value of the depot delay time when it is viewed as a constant. The basic purpose of the experiment involving these three cases is to demonstrate the importance of using knowledge of the wholesale echelon, specifically the item-specific depot delay times, in computing retail allowances.

Table 7

EVALUATION OF CASES 2 AND 3

	Aircraft Availability						
	Retail Only	Case 1 DDT = 0	Case 2 DDT = 23	Case 3 DDT = 45	"Navy"		
		Pe	acetime				
Pooled	88	89	88	84	74		
NAS	86	87	86	81	75		
CV 95 95 94 91					72		
		Wa	rtime	•			
Pooled	74	47	56	58	34		
NAS	74	46	58	60	36		
CV	74	50	52	51	32		

Interestingly, for the "Navy" stockage posture, depot delay times range from less than a day to more than 340 days (although only four of the 552 items in our data base had values over 200 days), with a weighted mean of 22.8 days. It seems intuitively clear that such dramatic heterogeneity should not be ignored in determining retail allowances. For the wholesale stockage posture of the balanced multi-echelon case, on the other hand, the weighted mean depot delay time is 8.6 days, with individual delay times ranging from two days to 249 days (with only one item over 200 days), and the wholesale investment level is actually somewhat less.

A COMPARISON OF THE CHARACTERISTICS OF THE "NAVY" AND BALANCED MULTI-ECHELON STOCKAGE POSTURES

A comparison of some of the numerical and performance characteristics of the stockage postures resulting from the "Navy" and the balanced multi-echelon methods is illuminating. These two stockage postures are listed item by item in Appendix E. Perusal of the list provides some additional intuition about the two approaches. There are 552 items in the data base used in this demonstration. Table 8 compares the range, depth, and fill rates of the two postures. Table 9 shows how the balanced multi-echelon technique dominates the "Navy" technique in terms of the numbers of line items with greater, equal, and less depth. The differences at the retail level are especially striking.

It is interesting to note that the fill rates for the balanced multi-echelon posture are uniformly higher than for the "Navy" posture despite the fact that the performance was optimized with respect to aircraft availability rather than fill rate. This result is consistent with other demonstrations of multi-echelon stockage optimization techniques we have seen. Relative to a fixed safety-level policy, a multi-echelon stockage optimization algorithm will give up a few of the highest cost items in favor of stocking more of a large majority of less expensive items. Thus the fill rate of the inventory system as a whole tends to be substantially improved.

Table 8

COMPARISON OF "NAVY" AND BALANCED MULTI-ECHELON STOCKAGE POSTURES

	Metric	"Navy"	Balanced Multi-Echelon
Rang	e (Line items stocked)		
	Wholesale	408	449
	NAS	290	522
	CV	250	508
Dept	h (Total units stocked)		
	Wholesale	9303	10914
	NAS	1166	2651
	CV	871	2353
Fill	Rate (Peacetime)		
	Wholesale	0.922	0.939
	NAS	0.879	0.902
	CV	0.933	0.988
Fill	Rate (Wartime)		
	Wholesale	0.564	0.591
	NAS	0.722	0.818
	CV	0.837	0.933

The experienced Navy reader will have noted that the fill rates shown for the "Navy" case in peacetime are considerably higher than those actually observed in the fleet. There are probably several reasons for this imperfect emulation on our part. The difference at the wholesale level may be due largely to the fact that the "Navy" stockage posture includes all authorized war reserve stocks. At the retail level, the difference is less obvious. It may simply be due to the

assumption on our part that the total "requirement" is fully funded up to the level of the allowances computed. As mentioned previously, the computation was done using the shortage costs shown in Appendix D.

A Final Word on the Demonstration

In Section II we discussed the Navy's widespread use of demandbased stockage policies and their effects on range, cost, and performance. The differences in the two stockage postures discussed above suggest how a coherent, system-level view of the stockage problem might affect the cost and performance characteristics of the inventory. With the use of an aircraft availability objective function and a multiechelon optimization model sensibly applied, the problem of demand criteria disappears. One need not specify range additives, war reserve stocks, numerical stockage objectives, or other "band aids" to otherwise inadequate demand-based policies. (We do not mean that there is no need for additives outside the computation.) With the appropriate formulation, the optimization algorithm can take explicit account of weapon system complexity, item commonality, levels of indenture, military essentiality, and other item and system characteristics in computing stock levels. All of these capabilities are within the state of the art of modern multi-echelon inventory theory [10].

Despite the simplicity of this demonstration, it illustrates the contrasting attributes of the Navy's current stockage computational techniques and several alternatives, the examination of each of which has some instructive value. However, except for the graphs of time-related availability in Figures 2 and 6, it may fail to convey the vital need to take a count of scenario dynamics in evaluating the performance of stockage postures and setting availability goals and investment levels. This kind of evaluation is also within the state of the art. The Dyna-METRIC model and other models have the capability to estimate the performance of a stockage posture over time in dynamic combat scenarios. It is clear that such evaluations need to be performed routinely because they bring a wartime focus to the stockage problem and assist decisionmakers in goal setting. More importantly, such capability assessment tools help clarify the implications for military capability of alternative investment levels. This is the kind of

Table 9

COMPARISON OF LEVELS BY LINE ITEM

Wholesale Levels by Line Item

"Navy" level less	505
Total line items	552

integrating mechanism for which we specified the need in Section I.

Lest we convey the impression that implementation of these ideas is straightforward or that they can safely be assumed to be capable of delivering dramatic gains in performance with certainty, we hasten to add that there are some important problems still unsolved that may significantly influence the efficacy of these techniques. We discuss these problems in Sections IV and V.

CONCLUSIONS

The differences pointed out in Tables 8 and 9 are large--dramatic in fact--given that they represent equal-cost alternatives. We wish to reemphasize our earlier caveat about not translating the results of this simple demonstration directly to the "real world." Nevertheless, the magnitudes of several of the results suggest that the Navy might be able to achieve substantial improvements in weapon system availability with current levels of investment. The demonstration also suggests several other important observations:

- A stockage computational method based on realistic wartime scenarios will deliver better performance than one based on peacetime flying hour programs with war reserve, range, and other additives.
- The partition that exists between retail and wholesale stockage computations in the Navy seriously inhibits cost-effective solutions.
- If retail and wholesale stockage computations must be done separately, it may be important to future system improvement initiatives that the gains achievable through optimization of wholesale reorder levels are seriously constrained by retail allowances; bigger gains are achievable at the retail level but depend on a multi-echelon view.
- The use of an aircraft availability objective function coupled with a multi-echelon optimization algorithm is clearly superior to the Navy's current computational methods.
- Any stockage computational method should be used jointly with a
 capability assessment model that explicitly accounts for the
 dynamic character of wartime scenarios to estimate the wartime
 performance of the resulting stockage posture.¹

Dyna-METRIC, the model used in the evaluations portrayed in Figures 2 and 6, is especially useful in evaluating stockage posture performance in combat scenarios in which activity levels and other scenario characteristics change over time. It is described in [8].

- The use of an optimization algorithm that computes an availability/cost relationship is much more useful than one that depends on specification of a Lagrangian multiplier because the latter type yields only one solution for each value of the multiplier and inhibits the allocation of resources across weapon systems.²
- A multi-echelon optimization algorithm that maximizes pooled availability cannot be applied in a straightforward manner to the Navy's stockage computational problem, even if it accounts for heterogeneous distributions of end items, because it penalizes sites with smaller numbers of aircraft. It must also provide for separate optimization of AVCAL and OSI allowances. This will allow for provisioning each CV and NAS separately in addition to enabling availability rates to be balanced as desired among retail sites, while still achieving most of the advantage of the multi-echelon technique.

The logic underlying this demonstration can be extended to the initial provisioning problem [11] as well as to stockage problems involving consumables.

In the sections that follow, we discuss several of the issues involved in moving toward the improved computational methods discussed here. Several are of a technical nature and seem quite tractable; unfortunately, the technical issues seem overshadowed by the levels of uncertainty in resource demands that we have observed in the current system. This uncertainty has implications for stockage computational techniques that must be accounted for.

² Such an algorithm is described in [10].

IV. IMPLEMENTATION ISSUES

The Naval Supply Systems Command is in the midst of an important initiative involving modernization of its electronic data processing systems and, eventually, enhancements to the data bases and management information and computational systems they support. These initiatives, called resolicitation and resystemization, respectively, provide a unique opportunity for change. Perhaps the Navy could move toward implementation in the resystemization time frame of improved stockage computational methods although, admittedly, such a goal is ambitious. In this section, we discuss some of the technical issues that need to be resolved before implementation of improved stockage computational methods.

METHODOLOGICAL ISSUES

The specific details and configuration of the computational software that is in some sense "best" for naval aviation stockage computations is still a matter of uncertainty. Our experience and intuition suggest that, in general, it should have the features discussed in Section III. However, several design considerations have not been explicitly discussed. Among these considerations are those involving cannibalization, military essentiality, the inclusion of consumables (i.e., the modeling of (S,s) reorder policies), and the forecasting problem.

Cannibalization

The dimensions and performance characteristics of the stockage posture that emerges from a particular stockage computational technique depend heavily on the assumption about cannibalization that underlies the computation. Stockage postures that are based on the assumption of perfect consolidation of shortages tend to lack range, and their relatively higher estimates of performance depend on cannibalization. Obviously, though, not all aircraft components can be cannibalized. Thus the choice to be made as a matter of policy seems to be between the

random shortages assumption and a cannibalization assumption coupled with a data base that reflects the likelihood that a component can be cannibalized successfully and, perhaps, the estimated cost of doing so. In other words, a cannibalization assumption seems too optimistic without taking account of the fact that some components cannot or should not be cannibalized. It seems somewhat imprudent to assume any cannibalization in computing spares requirements; however, components with large numbers per aircraft probably should be undervalued to some extent since one cannibalized aircraft can yield the entire quantity per aircraft of an item's application.

The performance of a stockage posture should be evaluated both with and without the cannibalization assumption. A stockage posture that performs poorly without cannibalization will be improved more by cannibalization than one that performs well without it. Thus when cannibalization is assumed in an evaluation, the performances of two stockage postures may be almost indistinguishable when in fact they perform very differently without cannibalization.

What this logic suggests is that the stockage posture whose performance is poor without cannibalization depends on cannibalization to yield acceptable levels of performance in the operational world. The use of computational methods that result in such stockage postures implicitly shift some unknown but perhaps unacceptable share of the support burden from supply to maintenance, especially if the observations made in Section III turn out to be translatable to the operational environment.

There are unresolved issues affecting the choice of cannibalization policy. A reasonable policy might be to code for each component the probability of successful cannibalization along with its cost, and compute stockage postures in a way that explicitly accounts for those component characteristics. If such a scheme is not feasible, it seems imprudent to assume any cannibalization.

Military Essentiality

The Navy is currently involved in coding all aviation components with respect to military essentiality. Each component will be assigned a number between zero and one to describe its essentiality. Appendix C illustrates how simply the essentiality code can be included in the aircraft availability objective function of a stockage computational model, in this case one that assumes random shortages of items over aircraft. Military essentiality is a simple modeling problem; its difficult aspect lies in specifying truly meaningful essentiality codes.

The ability of an optimization algorithm to achieve higher availability for equal investment lies in its strategy of giving up a few very high cost items and stocking many more of the lower cost items, thus gaining advantage in both range and depth. However, if the highest cost items are the most essential, the optimization can be self-defeating. Thus such an algorithm should be coupled with a data base that accurately reflects item essentiality.

Modeling (S,s) Reorder Policies

The demonstration in this Note included only repairable items the reord r policy for which is assumed to be (S,S-1); i.e., the economic order quantity at the retail echelon is assumed to be one unit of stock. We approximated order quantities greater than one at the wholesale level by increasing the variance of the number of units in resupply at the wholesale level by the variance of a uniform distribution from zero to the reorder quantity. The same technique may be appropriate for the retail level.

An alternative approach is to separate the computation of repairables from that of consumables but to estimate the effects of shortages of consumables on aircraft availability and include that estimate in the repairable computation. This is a research issue that needs resolution but is beyond the scope of the present work.

The Forecasting Problem

Another problem that remains unsolved is the problem of forecasting future values of item and system characteristics. The problem is simple to describe but difficult to solve. It is that the computation one makes today is based on past observations and, perhaps, some predictions of the future. If a mix of spares is ordered now based on those observations, it will almost inevitably be the wrong mix when the spares are finally acquired because the future will eventuate in ways that we cannot predict. It is important, as we said before, that the data base that supports spares computations be as realistic a model of the future as we know how to make it.

But even if we are exceptionally conscientious in maintaining the data base, item characteristics evolve in ways that we simply cannot foresee. Items disappear entirely from the data base; new items appear; and item removal rates, BCM rates, procurement prices, repair times, and other characteristics change. It is important that the problem of characterizing such changes be solved because of the need to program funds for the provisioning and replenishment of spares. The leadtimes involved are such that the forecasting problem underlies the inability of the system to reach the right decisions about either investment levels or mixes of spares, and the further in the future the point in time is for which we try to estimate the availability-cost relationship, the more inhibiting the lack of a solution to the forecasting problem becomes.

What is needed is the ability to characterize statistically how the data base might change as time passes. If that were possible, it might also be possible to generate random realizations of data bases that would be representative of possible futures and that could support estimates of availability-cost relationships as they might be computed at future buy points. Such an approach would enable the kinds of techniques discussed in Section III to be very useful in planning, programming, and budgeting as well as in the computations of levels and requirements. They could bring consistency to the decisionmaking about availability goals and investment levels across the several stages of PPBE&M, the need for which we discussed at length in Section I.

The Computational Software

The results of the demonstration of Section III suggest that a stockage computational algorithm for naval aviation should:

- Be multi-item, multi-location, multi-echelon, and multiindenture.
- Encompass both repairables and consumables.
- Account for item commonality.
- Incorporate a weapon system availability objective function.
- Produce an availability-cost curve by weapon system, each point
 of which is an optimum, rather than relying on a Lagrangian
 function.
- Account for heterogeneous distributions of end items.
- Have the ability to compute stockage postures for individual retail sites with visibility of item-specific depot delay times.
- Accommodate a cannibalization assumption for those items specified by policy.
- Provide decision support for the allocation of resources and goal setting across weapon systems.
- Model item-specific variance-to-mean ratios of the distribution of the number of items of each type in resupply.
- Be coupled with a data base that reflects both military essentiality and cannibalization data as well as the necessary
 3M and program data elements needed to support the multiechelon computation.
- Be routinely used in practice with a capability assessment model that takes explicit account of the dynamic character of combat scenarios.

With some modifications (for cannibalization, consumables, and heterogeneous end item distribution), the LMI Aircraft Availability Model would satisfy all of these criteria. Moreover, the latest version of Dyna-METRIC could be used for capability assessments both with and without cannibalization, either complete or partial. We do not wish to

advocate particular models; however, there are clearly some advantages to be gained in adapting existing, computationally efficient models to the problem rather than starting from scratch. Except for validation in the naval aviation context, the task of developing the logic of computational algorithms is modest. Clearly, neither of these models is suitable for direct installation in production systems but could provide the computational algorithms and logic for production versions.

DATA BASES

No single Navy data base can support a multi-echelon computation. What is needed is a combination of program data, wholesale and retail supply data, and 3M data. Thus several data files need to be brought together to produce the data base that is needed. Perhaps the most important single conclusion of this work is that, as an absolute minimum, the Navy needs to provide item-specific depot delay times to the computation of retail allowances. That visibility, coupled with an aircraft availability objective function, optimization algorithm, and realistic wartime scenario, could yield the most significant gains in performance of any of the changes discussed in this Note.

SCENARIOS

The estimated performance of every alternative stockage computational technique examined in Section III was superior to the "Navy" method, even those that were considerably less than "optimal." An important reason for this is that the higher aircraft utilization rates postulated for the wartime scenario were used as the basis for the computations in all but the "Navy" case. In the "Navy" approach, the peacetime flying hour program is the basis of the wholesale computation; then war reserve stocks are added. The result seems quite predictable. A stockage posture that is optimized for the higher activity level will perform better at that activity level than one that is not. Thus wartime scenarios should be used for computing stockage postures throughout the system.

This logic has implications for war reserve stockage policy. In a stockage optimization computation done at wartime activity levels, war reserve is essentially built into the resulting stockage posture rather

than being added to it after the fact. It may be desirable, however, to protect some stock against depletion in peacetime due to extreme variability in the numbers of items in peacetime resupply. Inviolate war reserve levels could be established on the basis of two successive stockage optimizations, one at the wartime activity level and one at the peacetime activity level, the differences in the resulting stockage postures being identified as war reserve.

V. UNCERTAINTY AND ITS IMPLICATIONS FOR AVIATION LOGISTICS

In this section we broaden our focus from spares stockage computational issues to the total logistics system. We begin with some observations of variability in resource demands. During the course of this research, we examined 3M data on several arbitrarily selected, WRAs on the F-14 aircraft. The data revealed levels of variability in component removal rates far beyond the levels planned for in determining allowances. This finding, however preliminary and tentative, implies the need for enhanced flexibility and responsiveness in aviation logistics as well as different views of stockage policies and spares requirements determinations.

OBSERVED VARIABILITY IN DEMAND

The findings reported here are based on 3M data collected at NAS Oceana and Miramar during the 28-month period from August 1981 through November 1983, and from two consecutive deployments of each of two CVs, the U.S.S. Nimitz and the U.S.S. Eisenhower, all four of which took place during the same 28-month period. The work unit codes (WUCs) included in this analysis were chosen quite arbitrarily from among weapon-replaceable assemblies on the F-14 aircraft.

The data consisted of detail records reflecting on-aircraft component removals for cause, i.e., no-defect removals were excluded. The data set contained the date of each removal action, by bureau number, by location. The data were arranged chronologically by location, and grouped into complete weeks, months, and quarters. Then the mean removal rate and variance were computed by week, month, and quarter. Finally, the unbiased estimate of the variance was divided by the unbiased estimate of the mean, and the ratio used as an estimator of the variance-to-mean ratio (VTMR) of the component removal process. Unfortunately, this estimator is not only biased for certain processes, it also has very high variance [12].

 $^{^{1}}$ The specific rules used for the selection of records are described in Appendix F.

The computation of retail allowances is based on the classical assumption of a simple Poisson process. Under this assumption the variance of the demand distribution equals its mean, i.e., the VTMR is unity. This assumption is important to the computation of safety levels as well as estimates of stockage posture performance characteristics such as fill rates, expected backorders, operational rates, and weapon system availabilities. It is a measure of the uncertainty of demand. The higher the VTMR, the less predictable the demand.

For purposes of exposition, we show in Table 10 data from NAS Oceana. Similar results are shown for other locations in Appendix F. Note that the estimated VTMR increases as a function of the time period over which the data are aggregated. This is partially explained by the fact that the VTMR estimator is biased, and the amount of its bias decreases with the length of the time period; however, there are other factors operating here, for example, nonstationarity in the component removal process, batching of removals by maintenance, or, perhaps, data problems. Thus the significance of the VTNRs shown in Table 10 is not clear. The estimates based on quarterly data are probably better approximations than those based on the shorter time periods; on the other hand, the estimates based on longer periods are more susceptible to errors induced by changes in location parameter.

The results shown in Table 10 are corrected for flying hours in Table 11. The correction makes a significant difference which suggests that variability in flying activity plays some role here, but, in the quarterly data, 19 of the 26 components still have variance-to-mean estimates at least twice the value assumed in the computation of retail allowances, and the estimator, as pointed out previously, is negatively biased.

The quantification of VTMR may have little intuitive meaning to the reader. To illustrate the point we are trying to make here we show in Figure 7 a graph of the number of removals per quarter of work unit code 56X21 for the nine-quarter period of the data set, again using the Oceana data. What this graph portrays is the actual number of removals for

Table 10

cause of this work unit code in each of the nine quarters, and also portrays a random realization of a process with the same mean and a VTMR of unity. In other words, we contrast the actual component removal process with a "planned" process in the sense that the variability of the planned process is of the order of magnitude assumed in the computation of retail allowances. We do not know what mean might have been used for any particular provisioning of this component; therefore, we use the same mean for the "planned" process as observed in the actual process. The contrast is stark and shows the fallacy of the Poisson assumption.

THE IMPLICATIONS OF UNCERTAINTY

The implication of variability of this magnitude is that it is very difficult to forecast demands, even in the short term. Yet the system presupposes the ability to make such forecasts, and behaves as though past demands predict future demands and peacetime demands predict wartime demands. The uncertainties in the system even in peacetime refute that supposition. Moreover, the uncertainties in peacetime will be compounded by the disruptions, resource losses, and inevitable surprises of combat. They cast doubt on the wisdom of depending on a spares solution alone to the problem because of the substantially higher

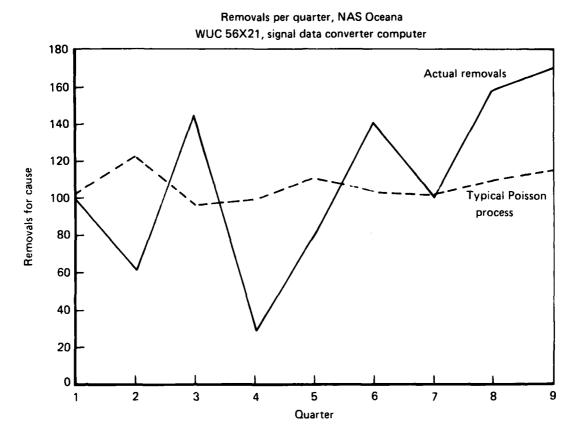

Fig. 7 – Quarterly removals, WUC 56X21, and a typical Poisson process

costs associated with stockage postures that try to provide a hedge against the demand variability. Thus the need exists to examine other solutions involving more flexible resources than spares, such as maintenance and distribution/transportation.

Demand uncertainty of this magnitude implies the need for enhanced flexibility and responsiveness in the naval aviation logistics system which presupposes a level of integration that the Navy does not now enjoy. Thus the thrust of this work in stockage computational techniques should be viewed in the broader context of the enhanced integration needed in the system as a prerequisite of sorts to improving the system's flexibility and responsiveness. Its implications in the larger context are both for aviation supply within itself and for the interrelationships between supply and other functional areas.

But what of the implications for stockage computations of the levels of demand variability we have shown here? No matter how responsive the system can be made, the stockage computational problem never disappears. There will always be a need for spares. The question is how to formulate a reasonable set of assumptions on which to base the computational approach, including assumptions that take advantage of what we know about demand variability. One of the factors that contributed to the better performances of the alternative techniques demonstrated in Section III over the "Navy" method is that the alternative methods do not make the simple Poisson assumption in computing retail allowances. Instead, they assign a variance-to-mean ratio to the distribution of the number of items in resupply of each type that was related to the item's mean demand rate according to the formula described in Appendix B, i.e., the assigned variance-to-mean ratio was invariably greater than unity.

However, taking explicit account of higher variance-to-mean ratios in computing stockage postures yields higher estimates of investment levels for specified levels of weapon system availability. If the levels of variability we have shown here are pervasive, their use in stockage computations might very well put stockage solutions out of reach in terms of their costs. On the other hand, there may be a simple method for taking explicit account of demand variability in stockage computations in a way that does not make the solutions exorbitantly costly but does yield stockage postures that are sufficiently robust in the face of uncertainty. The solution to this problem is not clear. Additional analysis is needed to determine the extent and magnitude of the variability as well as its persistence over time. We also need to understand better the implications of the variability for stockage computations.

The cost of hedging against the levels of uncertainty that we have seen here might be more than offset by pursuing strategies that reduce item pipelines and that enhance the selective responsiveness of the system to unanticipated demands. In other words, system performance might best be enhanced by *combinations* of techniques that (a) take explicit account of uncertainty in stockage computations, (b) reduce

component repair times, order-and-ship times, and retrograde times, and (c) enhance the ability of the system to respond selectively to unanticipated demands in ways that contribute best to the combat posture of the fleet. Thus the observations made here about demand variability do not necessarily mean that optimization models are inappropriate for use in stockage computations because of the difficulty in forecasting demand. They simply imply that we need to understand the character of the variability better as well as its implications for stockage computations, and that solutions should be sought in other areas as well as in supply.

This argument is reinforced by the fact that the uncertainties the system faces in peacetime are compounded by the uncertainties of combat. The reduction of item pipelines and an enhanced ability to respond to unanticipated demands, coupled with improved stockage computational methods, can mitigate the effects of those uncertainties.

VI. TOWARD ENHANCED INTEGRATION AND RESPONSIVENESS IN AVIATION LOGISTICS

The Navy needs to establish a program of research and development that will help it move toward enhanced integration and responsiveness in aviation logistics. The areas of research should include: enhanced system integration through capability assessment; improved spares stockage computational techniques; and more responsive repair, distribution, and transportation systems. The specific objectives of this research program should be to:

- Implement capability assessment techniques at key decision points throughout naval aviation, including stockage determinations, to enhance system integration.
- Understand better the implications of uncertainty on the stockage computational problem.
- Develop multi-echelon spares stockage optimization models for computing wholesale reorder levels and retail allowances that maximize weapon system availability and that are consistent with the outcomes of the research in uncertainty mentioned above.
- Develop integrated data bases that bring together the data required to support such computational techniques including military essentiality data.
- Develop strategies for improving the responsiveness of depot repair and distribution/transportation, thus coupling the depot more closely to the combat force to meet unanticipated critical demands more responsively.

As pointed out previously, demand uncertainty implies the need for enhanced flexibility and responsiveness in the naval aviation logistics system, responsiveness which presupposes a level of integration that the Navy does not now enjoy. Thus the work being proposed here should have as its basic thrust two principal goals:

- Enhancement of integration through systemwide capability assessment and improved stockage computational techniques.
- Enhancement of flexibility and responsiveness throughout the system, but especially in depot-level component repair and distribution/transportation.

A RESEARCH AND DEVELOPMENT PROGRAM

The objectives of this work could be met through three major tasks that we recommend the Navy undertake, two of which are concerned primarily with integration, and one with responsiveness.

Task 1: Enhancing Integration Through Systemwide Capability Assessment

In this task, the Navy would undertake the first steps toward enhancement of aviation logistics system integration and oversight through initiation of capability assessments. These assessments would be used by key decisionmakers throughout the operational logistics system to support the consistency in decisionmaking for which we described the need in Section I. The steps involved would be:

- Acquisition of data by NAVAIR to support the assessment of both the peacetime and wartime weapon system sortic generation capability of a major weapon system, both afloat and ashore.
- In concert with at least one TYCOM and the ASO weapon system management organization, completion of this prototype assessment by NAVAIR.
- Analysis of the results of the assessment to identify resource constraints, problem parts and causes, and related policy issues, as well as technical problems in conducting the assessment.
- Based on successful completion of these initial tasks, identification of specific steps to be taken to implement capability assessment techniques at key decisionmaking points in the system.

 Additional technical support and training of Navy personnel as required to assure a smooth transition to routine maintenance, support, and use of the techniques at key decision points throughout the system.

This approach could be expected to:

- Identify quickly what the key implementation issues are, e.g., data quality and accessibility.
- Support aviation logistics planning in a useful and constructive application.
- Demonstrate the ability of capability assessment techniques to make a genuine contribution to enhancement of aviation logistics system integration.
- Provide the Navy with the needed ability to bring combat capability orientation to its key decisionmaking.

Task 2: Improving Spares Stockage Postures

The observations of demand uncertainty shown in Section V are persuasive, but the analysis needs to be extended because the implications to capability are so important. Additional analysis is needed to provide evidence on the pervasiveness, magnitude, and persistence of the variability, and the ability of the current system to cope with it.

This task would involve understanding better the character of the variability and its implications to the stockage computational problem, as well as the analysis of the implementation issues discussed in Section IV. This research would be followed by or coupled with the development and implementation of multi-echelon spares stockage computational models that maximize weapon system availability and explicate availability/cost relationships to support resource allocation decisionmaking as well as stockage posture determinations. It would involve the development of computational algorithms having the characteristics described in Section IV. Following the research phase described above, the several steps involved in this task would be:

- Development of an integrated data base that would bring together 3M data, program data, and supply data to support a multi-echelon availability optimization.
- Specification of military essentiality and cannibalization coding and inclusion of those codes in the data base.
- Enhancement and adaptation of a model such as the LMI Aircraft Availability Model so that it explicitly accommodates military essentiality, cannibalization, (S,s) reorder policies, heterogeneous end item distribution, and separable optimization of AVCAL and OSI stockage postures.
- Calibration of the model to the naval aviation environment.
- Implementation of the model coupled with implementation and routine use of the Dyna-METRIC model or a similar model for estimating the performance of stockage postures in combat scenarios.

Task 3: Enhancing Responsiveness in Distribution/Transportation and Depot-Level Component Repair

In this task the Navy would:

- Analyze the current logistics system to determine the nature of demand and pipeline variability and the lengths of all segments of the logistics pipeline, with special attention to the orderand-ship, retrograde, and depot repair segments.
- Determine how well (and in what ways) the current system responds to urgent demands--both anticipated and unanticipated--in order to understand the implications to both cost and effectiveness of (a) enhanced selective response to unanticipated demands and (b) reductions to pipeline times.

The following tasks are likely to emerge from these initial efforts:

- Assessment of the distribution/transportation system to identify alternatives that could improve its responsiveness and shorten pipeline times for both serviceable and retrograde spares and other logistics resources, and estimation of the gains achievable.
- Assessment of the depot-level component repair system with the similar goal of identifying alternatives that could improve its responsiveness to demands from the fleet, and, again, estimation of the gains achievable.
- Determination of the applicability of identified alternatives to intermediate-level repair activities.

CONCLUDING REMARKS

In this Note, we have tried to demonstrate:

- The worth of an aircraft availability objective function coupled with a multi-echelon optimization algorithm and integrated data base in stockage computations.
- The need for enhanced flexibility and responsiveness in the system implied by the levels of demand variability observed in peacetime which, when compounded with the uncertainties of combat scenarios, inhibit effective support.
- The value of reducing item pipelines in conjunction with improving stockage postures in mitigating the effects of uncertainty, especially in combat scenarios.

The use of improved techniques of the kind described in this Note can move the aviation supply community toward more ultimate, capability-oriented measures that have operational meaning throughout the system. Moreover, those techniques can be expected to deliver substantially improved performance at current levels of investment in both peacetime and wartime, and enhance both intrafunctional and interfunctional supply system integration.

Appendix A

EMULATING THE NAVY'S STOCKAGE COMPUTATIONS

At present the Navy separates its stockage computations by echelon. To emulate the Navy's methods, we employed two software modules: the first was based upon the Uniform Inventory Control Program and was used to generate wholesale stock levels; the second was an existing Rand model of the procedure used to determine OSIs and AVCALs.

In addition to scenario- and component-specific data, each module requires a number of performance-related parameters. In the case of the wholesale emulator, these are quantities such as shortage costs and bounds on stockout risk. In our demonstration, we used values identical to those established by ASO for the September 30, 1983, Strat run. These are discussed in greater detail in Appendix D. The OSI/AVCAL emulator requires a fill rate goal and a target endurance period, as well as a specification of whether or not safety stock is to be added. We postulated a fill rate of 0.85 for both naval air stations and aircraft carriers, and endurance periods (including order-and-ship time) of 40 days for shore stations and 105 days for carriers. As does ASO, we added safety stock to the repair pipeline only.

The FORTRAN code for both emulators is given below. In each case, extensive comments have been provided to aid the understanding of interested readers.

EMULATING THE NAVY'S WHOLESALE REORDER LEVEL COMPUTATIONS

EML	JLATING THE NAVY'S COMPUTATION OF RETAIL ALLOWANCES
С	
С	PROGRAM AVCAL.EMULATOR (the OSI/AVCAL emulator)
С	
С	PROGRAM TO CALCULATE THE AVCAL - EMULATED METHODOLOGY
С	THE FOLLOWING PROGRAM WILL BE USED TO CALCULATE STOCKAGE
С	FOR THE CABAL STRUCTURES, IN SUCH A WAY AS TO EMULATE THE
С	NAVY AVCAL PROCESS. THE DATA IS ASSUMED TO BE SORTED IN NIIN
С	SEQUENCE.
С	
С	1. INPUT DATA
С	SEVERAL TYPES OF RECORDS WILL BE READ INTO THE
C	PROGRAM. THE FIRST RECORD TYPE (OF WHICH THERE WILL
С	BE ONLY ONE RECORD) DESCRIBES THE PROGRAM RUN TO
С	BE MADE AND GIVES SOME GLOBAL PARAMETERS. IT
С	CONTAINS
С	SHIP FRTARG TA ECHO SLEV
С	SHIP = SHIP OR SHORE STOCKAGE (1 = SHIP, 0 = SHORE)
С	FRTARG = FILL RATE TARGET FOR FILL RATE CALCULATION
С	TA = ENDURANCE PERIOD TARGET FOR ATTRITION
С	CALCULATIONS
С	ECHO = 1 IF DATA ECHO IS DESIRED, O OTHERWISE
C	SLEV = 1 IF SAFETY LEVEL ADDED, O OTHERWISE
С	
С	
С	THE SECOND RECORD TYPE DESCRIBES THE PLANNED FLYING
С	ACTIVITY OF THE VARIOUS AIRCRAFT TYPES. IT IS REPEATED
C	AND EACH AIRCRAFT TYPE AND CONTAINS
C	TMSK FHK NAK
С	TMSK = NAME OF THE AIRCRAFT TYPE K
C	FHK = FLYING HOURS PER AIRCRAFT PER DAY FOR AIRCRAFT
С	TYPE K
С	NAK = NUMBER OF AIRCRAFT OF THIS TYPE
С	
С	RECORD TYPES 1 AND 2 ARE READ AS IN STREAM INPUT DATA.

С	
С	
С	THE THIRD RECORD TYPE CONTAINS COMPONENT DATA
С	USED FOR STOCKAGE CALCULATION AND COST BREAKDOWNS.
С	IT IS REPEATED FOR EACH COMPONENT (AND SEVERAL TIMES
C	FOR COMPONENTS WHICH HAVE MULTIPLE (OLS) AND LOOKS
C	AS FOLLOWS:
C	NIIN IOL CCODE QPA PTYP C TS BCM MBAR DETREP
С	FOR A SINGLE COMPONENT TYPE (THAT IS FOR A NIIN) THE
С	ONLY DATA VARIATION BETWEEN RECORDS SHOULD BE THE IOL,
С	QPA, AND THS. THE DEFINITIONS OF TERMS ARE:
С	NIIN = NATIONAL ITEM IDENTIFICATION NUMBER FOR
С	COMPONENT(NIIN(J), J=1,3)
С	IOL = IOL THIS PART APPLIES TO
С	CCODE = COMPONENT CODE
С	QPA = QUANTITY PER APPLICATION
С	PTYP = PART TYPE: $1 = WRA$, $0 = SRA$
С	C = UNIT COST OF THE COMPONENT(\$)
C	TS = SHIPBOARD TURN AROUND TIME
С	(LOCAL, AI, AND REPAIR TIME IN DAYS)
С	BCM = FRACTION OF COMPONENTS DEMANDS BEYOND
С	CAPABILITY OF MAINTENANCE AT THE SHIP
С	MBAR = DEMANDS PER FLYING HOUR
C	DPTREP = DEPOT REPAIR TIME (DAYS)
C	
С	COMPONENT DATA ARE READ FROM UNIT FT08.
C	
C	
C	2. GENERAL PROCESSING
C	THE FIRST STEP WILL BE TO READ ALL RECORDS OF TYPE
C	1 AND 2 AND STORE INTERNALLY. THE REMAINING PROCESSING
C	WILL BE GENERALLY AS FOLLOWS:
C	I. READ ALL RECORDS OF TYPE 3 ASSOCIATED WITH A
С	SINGLE NIIN AND STORE THE DATA INTERNALLY.
C	II COMPLETE THE TOTAL DOOL OF THE SECTION OF THE

VARIANCE-TO-MEAN RATIOS

The VTMR of component pipeline quantities is often used as a measure of uncertainty. Under the classical assumption of Poisson-distributed demands, the VTMR for each component is equal to one; however, several empirical studies suggest that in most cases of interest, the VTMR exceeds one.

Our efforts to obtain historical VTMR values for the sample of 552 F-14 components used in this demonstration were frustrated by an apparently irreconcilable problem in the data file (drawn from the Navy's Selected Item Extract Generator). We found VTMRs ranging from below zero (impossible) to over two million (highly implausible). Rather than basing our comparison of computational methods upon such suspect numbers, we turned to the use of an estimation technique proposed by Sherbrooke [13] in which the VTMR for component i takes the form

$$VTMR = 1 + am_{i}^{b}$$

Here, \mathbf{m}_{i} denotes the mean pipeline size for component i, and a and b are values that depend upon the components in question. For recoverable components managed by the Air Force Logistics Command, Sherbrooke found a and b to be given by

$$a = 0.141 + 0.0125Q$$
, and $b = 0.583 - 0.0045Q$.

where Q denotes a forecasting period, in quarters. There is no compelling reason to suppose that these values hold in any universal sense; on the other hand, they seem reasonable. In this spirit, we arbitrarily selected a forecasting period of 10 quarters (a typical component procurement lead time) and rounded a and b to values of 0.25 and 0.5, respectively. In addition, we appended a third term to the expression for VTMR to account for components that are ordered in

quantities greater than one. Thus, we have

VTMR = 1 +
$$0.25m_{i}^{0.5} + OQ_{i}^{2}/12m_{i}$$

where OQ_i is the order quantity for component i. Finally, we specified an upper bound of 25.0 on all computed VTMRs; this, however, turned out to be of almost no consequence, as only two components were affected.

Appendix C

THE WEAPON SYSTEM AVAILABILITY METRIC

The use of weapon system availability both as the objective function and as the criterion of evaluation in the computation and comparison of stockage postures offers a number of advantages not found in the use of more traditional measures, such as supply materiel availability (SMA), or fill rate. Perhaps the most appealing of these is the focus on particular weapon systems rather than on inventory system performance. The availability of a weapon system is far more relevant in an operational sense than is SMA. In addition, it is possible to account for varying levels of weapon system complexity, so that, to some extent, the capability of the entire force can be kept in proper balance.

Weapon system availability may be defined as the probability that an aircraft selected at random is found to have no component shortages. If we assume that shortages of different components occur independently of one another, we may express weapon system availability, A, as

$$A = \prod_{i=1}^{N} q_{i},$$

where N is the number of different components comprised by the weapon system and \mathbf{q}_i denotes the probability that an aircraft selected at random has no shortage of component i. If we assume further that no effort is made in the direction of cannibalization, but instead, that shortages are distributed at random across all aircraft, we may estimate the probability of shortage for a particular installation of component i, \mathbf{p}_i , as

$$p_i = EBO_i/TI_i$$

where $\operatorname{EBO}_{\mathbf{i}}$ is the expected number of backorders for component i across

all aircraft and TI_i is the total number of installations of component i across all aircraft. We may write q_i in terms of p_i :

$$q_{i} = (1 - AF_{i}) + AF_{i}(1 - P_{i})^{QPA}_{i}$$

where AF_i denotes the application fraction, or proportion of aircraft of a particular type that contain component i, and QPA_i denotes the quantity per aircraft of component i. We then have, as a final expression for weapon system availability,

$$A = \prod_{i=1}^{N} [(1 - AF_i) + AF_i(1 - EBO_i/TI_i)^{QPA}i]$$

This formulation follows closely the approach taken in the LMI Aircraft Availability Model, and is consistent with other well-known models, including Dyna-METRIC [10,8]. It should be pointed out, however, that for purposes of the demonstration discussed in this Note, no attempt was made to treat such features as levels of indenture and common components. While these are unquestionably important in everyday applications, we felt that they would needlessly complicate the illustration of the efficacy of the weapon system availability method. The interested reader is referred to the LMI paper for a more complete exposition of enhancements to the basic expression.

A frequent criticism of availability-oriented, marginal-analytic approaches to stockage computation is that they often suggest very heavy expenditures for relatively cheap components and a correspondingly light investment in expensive components. In practice, however, it is often the expensive components that are the most critical to aircraft mission performance. Therefore, such stockage strategies may be self-defeating in a sense.

This problem may be circumvented to a large extent by quantifying the mission essentiality of each component. The quantification of mission essentiality depends on more than simply the quantification of the importance of a component to the operation of a system or subsystem. It also involves failure mode analysis and the determination of the relationship between failures, component removals, and component demands. The Navy is now in the process of assigning essentiality codes to aircraft components. It is an important step in moving toward more realistic stockage postures.

Given a realistic determination of component essentiality, the problem of taking explicit account of it in stockage computations is simple and straightforward. If we let $\mathbf{s}_{\mathbf{i}}$, the essentiality of component i, vary from 0.0 (nonessential) to 1.0 (absolutely essential), we may use it as a weight for the expected backorder term. Thus, we may write the essentiality-weighted weapon system availability, A', simply as

$$A' = \prod_{i=1}^{N} \{(1 - AF_i) + AF_i(1 - s_i EBO_i / TI_i)^{QPA}i\}$$

Appendix D

AVIATION SUPPLY OFFICE SHORTAGE COSTS

Simply defined, the shortage cost of a weapon system component is the degradation in operational capability, quantified in terms of dollars, attributable to its absence. Shortage costs figure prominently in the current method of wholesale stockage computation employed by the Navy's Aviation Supply Office. Although from the definition above it may seem that they are measurable in some empirical fashion, shortage costs are in reality employed primarily as control parameters in the generation and assessment of alternative inventory policies. Using CARES, ASO can compare the effects of varying shortage costs on the basis of such performance criteria as mean delay time and SMA, or fill rate. The values that appear to furnish the best results can then be used in Levels and Strat to compute stock levels and budget projections.

Ideally, shortage cost would be a component-specific quantity. This would at the very least be impractical, however, in the context of ASO's present strategy of comparing different sets of values and selecting the best one. Clearly, the large number of components in the Navy's inventory system would preclude any sort of comprehensive evaluation. Therefore, ASO aggregates shortage costs by four-digit cognizance code. The values established for the September 30, 1983, Strat run are given below in Table D.1; also included are the limits on stockout risk that were used in the same computation [14]. Both the shortage costs and the limits on stockout risk were incorporated into our emulation of ASO's computation of wholesale stock levels.

COMPARISON OF STOCKAGE POSTURES

Among the several stockage computation techniques discussed in this Note, two are of primary interest: the emulated Navy method and the availability-balanced, multi-echelon method. A comparison of the equal-cost stockage postures produced by these methods reveals a number of rather startling differences in both range and depth; these are summarized in Section III.

Table E.1 contains a detailed breakdown by component of each posture, with stock levels given both for the wholesale echelon and for each of two types of retail locations (Naval Air Stations and aircraft carriers). In addition, component replacement cost is listed to illustrate more clearly the tradeoffs between high- and low-cost components made by the multi-echelon algorithm. It should be noted that the retail stock levels presented in Table E.1 correspond to the allowance for just a single site; in the actual computation, however, we provided for two air stations and four carriers.

Appendix F

DATA ON VARIANCE-TO-MEAN RATIOS

We include here some additional observations of component removals by month and location as well as the corresponding removal rates adjusted for flying hours. The data from which these observations were drawn were kindly provided by the Navy Ships Parts Control Center. They cover the 28-month period from August 1981 through November 1983, and include action-taken codes P and R (remove; remove and replace) coupled with how-malfunctioned codes other than 799 through 811. The time period was specified so as to cover two consecutive deployments of each of two aircraft carriers, the U.S.S. Nimitz and the U.S.S. Eisenhower. The Nimitz was deployed from August 1981 through January 1982 and from November 1982 through April 1983. The Eisenhower was deployed from January through June 1982 and from May through November 1983.

Table F.1 shows the unadjusted component removals aggregated monthly. Table F.2 reflects the component removal rates adjusted for flying hours.
